                                <1>     ; 16/04/2015 - 01/09/2015 (Retro UNIX 386 v1)
                                <1>     ; 19/04/2013 - 14/02/2014 (Retro UNIX 8086 v1)
                                <1>     ;
                                <1>     ; 'sysexit' terminates a process. First each file that
                                <1>     ; the process has opened is closed by 'flose'. The process
                                <1>     ; status is then set to unused. The 'p.pid' table is then
                                <1>     ; searched to find children of the dying process. If any of
                                <1>     ; children are zombies (died by not waited for), they are
                                <1>     ; set free. The 'p.pid' table is then searched to find the
                                <1>     ; dying process's parent. When the parent is found, it is
                                <1>     ; checked to see if it is free or it is a zombie. If it is
                                <1>     ; one of these, the dying process just dies. If it is waiting
                                <1>     ; for a child process to die, it notified that it doesn't
                                <1>     ; have to wait anymore by setting it's status from 2 to 1
                                <1>     ; (waiting to active). It is awakened and put on runq by
                                <1>     ; 'putlu'. The dying process enters a zombie state in which
                                <1>     ; it will never be run again but stays around until a 'wait'
                                <1>     ; is completed by it's parent process. If the parent is not
                                <1>     ; found, process just dies. This means 'swap' is called with
                                <1>     ; 'u.uno=0'. What this does is the 'wswap' is not called
                                <1>     ; to write out the process and 'rswap' reads the new process
                                <1>     ; over the one that dies..i.e., the dying process is
                                <1>     ; overwritten and destroyed.
                                <1>     ;
                                <1>     ; Calling sequence:
                                <1>     ;       sysexit or conditional branch.
                                <1>     ; Arguments:

                                <1>     ; 24/05/2013 - 05/02/2014 (Retro UNIX 8086 v1)
                                <1>     ;
                                <1>     ; 'syswait' waits for a process die.
                                <1>     ; It works in following way:
                                <1>     ;    1) From the parent process number, the parent's
                                <1>     ;       process name is found. The p.ppid table of parent
                                <1>     ;       names is then searched for this process name.
                                <1>     ;       If a match occurs, r2 contains child's process
                                <1>     ;       number. The child status is checked to see if it is
                                <1>     ;       a zombie, i.e; dead but not waited for (p.stat=3)
                                <1>     ;       If it is, the child process is freed and it's name
                                <1>     ;       is put in (u.r0). A return is then made via 'sysret'.
                                <1>     ;       If the child is not a zombie, nothing happens and
                                <1>     ;       the search goes on through the p.ppid table until
                                <1>     ;       all processes are checked or a zombie is found.
                                <1>     ;    2) If no zombies are found, a check is made to see if
                                <1>     ;       there are any children at all. If there are none,
                                <1>     ;       an error return is made. If there are, the parent's
                                <1>     ;       status is set to 2 (waiting for child to die),
                                <1>     ;       the parent is swapped out, and a branch to 'syswait'
                                <1>     ;       is made to wait on the next process.

                                <1>     ; 06/05/2015 (Retro UNIX 386 v1 - Beginning)
                                <1>     ; 24/05/2013 - 14/02/2014 (Retro UNIX 8086 v1)
                                <1>     ;
                                <1>     ; 'sysfork' creates a new process. This process is referred
                                <1>     ; to as the child process. This new process core image is
                                <1>     ; a copy of that of the caller of 'sysfork'. The only
                                <1>     ; distinction is the return location and the fact that (u.r0)
                                <1>     ; in the old process (parent) contains the process id (p.pid)
                                <1>     ; of the new process (child). This id is used by 'syswait'.
                                <1>     ; 'sysfork' works in the following manner:
                                <1>     ;    1) The process status table (p.stat) is searched to find
                                <1>     ;       a process number that is unused. If none are found
                                <1>     ;       an error occurs.
                                <1>     ;    2) when one is found, it becomes the child process number
                                <1>     ;       and it's status (p.stat) is set to active.
                                <1>     ;    3) If the parent had a control tty, the interrupt
                                <1>     ;       character in that tty buffer is cleared.
                                <1>     ;    4) The child process is put on the lowest priority run
                                <1>     ;       queue via 'putlu'.
                                <1>     ;    5) A new process name is gotten from 'mpid' (actually
                                <1>     ;       it is a unique number) and is put in the child's unique
                                <1>     ;       identifier; process id (p.pid).
                                <1>     ;    6) The process name of the parent is then obtained and
                                <1>     ;       placed in the unique identifier of the parent process
                                <1>     ;       name is then put in 'u.r0'.
                                <1>     ;    7) The child process is then written out on disk by
                                <1>     ;       'wswap',i.e., the parent process is copied onto disk
                                <1>     ;       and the child is born. (The child process is written
                                <1>     ;       out on disk/drum with 'u.uno' being the child process
                                <1>     ;       number.)
                                <1>     ;    8) The parent process number is then restored to 'u.uno'.
                                <1>     ;    9) The child process name is put in 'u.r0'.
                                <1>     ;   10) The pc on the stack sp + 18 is incremented by 2 to
                                <1>     ;       create the return address for the parent process.
                                <1>     ;   11) The 'u.fp' list as then searched to see what files
                                <1>     ;       the parent has opened. For each file the parent has
                                <1>     ;       opened, the corresponding 'fsp' entry must be updated
                                <1>     ;       to indicate that the child process also has opened
                                <1>     ;       the file. A branch to 'sysret' is then made.
                                <1>     ;
                                <1>     ; Calling sequence:
                                <1>     ;       from shell ?
                                <1>     ; Arguments:

                                <1>     NOTE:
                                <1>     ;* [u.pri] priority level is specified by run queue which is process
                                <1>     ;  comes to run from.
                                <1>     ;* Initial [u.pri] is 1 ('normal/regular') for programs
                                <1>     ;  (which are launched by MainProg or 'sysexec'), it is changed
                                <1>     ;  to 2 ('high') by timer event, if program uses 'systimer' system call.
                                <1>     ;* Program (Process) also can change it's running priority
                                <1>     ;  from 1 to 0 or up to 2 by using 'syspri' system call; but,
                                <1>     ;  if program selects priority level 2 (high) for running, next time
                                <1>     ;  it is reduced to 1 (normal/regular) because 'syspri' adds this
                                <1>     ;  program to 'run for normal' queue while running duration is a bit
                                <1>     ;  protected from swap/switch out immediate, behalf of other high
                                <1>     ;  priority process in sequence. Program (with high priority) will not
                                <1>     ;  be swapped/switched out (by timer event) before it's time quantum
                                <1>     ;  will be elapsed, but, this will be temporary if program is not using
                                <1>     ;  timer event function.
                                <1>
                                <1>     ;For example:
                                <1>     ;If a process frequently gets a timer event, it runs at high priority
                                <1>     ;level but when it returns from running it returns to actual run queue,
                                <1>     ;not to 'run for event' queue again.
                                <1>     ;'tswap' will not change the sequence at return/stop(swap out) stage.
                                <1>     ;But if priority level not high (=2, 'run for event'), 'tswap/tswitch'
                                <1>     ;will add the stopping process to relevant run queue according to
                                <1>     ;[u.pri] priority level.
